1 Abstract
The temperature dependence of barrier height and ideality factor values extracted from current-voltage (I-V) characteristics of a Ni/GaN Schottky contact at 50-400 K is evaluated using an adapted approach to Werner and Güttler’s parallel conduction model. Instead of assuming the lateral inhomogeneity at the interface takes the form of a single or multi-Gaussian distribution, it is shown that the non-ideal forward characteristics of the Schottky diode is best modeled by employing a single modified log-normal distribution. Further, it is shown that this approach can describe the voltage dependence of the lateral barrier distribution revealing that for effective barrier height values calculated at increasingly higher voltages, the distribution begins to converge on a single value of 0.77 eV. This value is in good agreement with the flat-band barrier height of 0.77±0.02 eV extracted from capacitance-voltage measurements on the same device. Finally, the same procedure is used to describe the parallel conduction path apparent at low temperatures, revealing its behavior is indicative of an additional Schottky region with an increased density of low barriers which are more heavily perturbed by external bias.

2 Highlights
- Effective barrier height and ideality factors extracted from I-V characteristics of Ni/GaN Schottky measured from 50 to 400 K
- Fitting procedure which uses a modified log-normal distribution is used to estimate the form of lateral inhomogeneity at the metal-semiconductor interface
- Barrier height distributions calculated at increased applied biases shows agreement with flat-band barrier heights extracted from C-V measurements
- Modeling applied to parameters extracted from parallel conduction region present at low temperatures reveals it origin is a separate Schottky interface with higher density of low barriers and increased voltage dependence

3 Introduction
Gallium nitride (GaN) has proven to be an excellent material to implement power semiconductor devices. This is largely because of its breakdown field strength, high temperature performance, and the availability of conductive substrates so that vertical device topologies are possible. Fabricated Schottky barrier diodes (SBDs) can act as both a high frequency and low turn-on voltage rectifying device and as a means of quickly evaluating the semiconductor material quality. On GaN however, the current-voltage (I-V) characteristics frequently deviate from ideal thermionic emission over a single barrier. These inconsistencies are typically attributed to a lateral variation in the barrier at the interface between the metal and semiconductor [1-3]. Carrier transport across this non-ideal interface has been analyzed with various models [4, 5] however, the continuous distribution model first discussed by Song et al. [6] and formalized by Werner and Güttler [7] presents a method by which the interface inhomogeneity can be characterized by a probabilistic
distribution without first having to make assumptions about the source of inhomogeneity. Ideally, if the cause of non-ideality can be accurately represented through these models, work can be done to link specific material growth and device fabrication methods to spurious electrical device behavior.

By first assuming that the fabrication of a real Schottky diode will have some lateral variation in the interfacial barrier height and that this variation takes the form of a Gaussian distribution, Werner and Güttler present a straightforward method to determine the mean and standard deviation of said distribution. Then, assuming a bias dependence of the effective barrier height distribution, they show that voltage dependence of the mean and standard deviation cause experimentally extracted values of ideality factor larger than unity. The technique was developed further using the same analysis method to describe interfaces with multiple non-interacting Gaussian distributions [8, 9] and then again using iterative solving techniques to describe interfaces with interacting Gaussian peaks [10]. Although these methods tend to provide agreement with experimental data, application to the sample presented in this work yielded results which did not fit the data or implied spurious behavior according to the underlying assumptions. It was found that instead of using a single or multi-Gaussian distribution model, a single modified log-normal distribution could be used. Additionally, work was done to understand the effect that voltage has on the barrier distribution, ultimately revealing that the log-normal distribution can be used to describe the interface as the diode approaches flat-band conditions. This process is then applied to the typically ignored low current parallel conduction path observed at low temperatures, revealing that it can be explained as stemming from a region of the M-S interface with a lower barrier and higher voltage dependence.

4 Inhomogeneous Schottky Model

The current ($I$) induced across a Schottky barrier diode (SBD) according to thermionic emission theory for an applied voltage ($V_A$) is given by the following equation [11]:

$$I(V_A) = A^* T^2 \exp\left(\frac{-q\phi_{b0}}{k_B T}\right) \left[ \exp\left(\frac{q(V_A - I R_s)}{\eta k_B T}\right) - 1 \right]$$

(1)

Where $A$ is the metal-semiconductor (M-S) contact area, $A^*$ is the Richardson constant of GaN ($26.4 \text{ A/cm}^2\text{K}^2$), $T$ is the temperature, $\phi_{b0}$ is the M-S interface barrier height at zero-bias, $\eta$ is the ideality factor, and $R_s$ is the series resistance. Werner and Güttler explain that the interface is likely not homogenous and perturbation due to surface roughness, metallic diffusion, and even dopant atom concentration abnormalities can create lateral variation in the barrier height [7]. The resulting I-V characteristics is thus a superposition of thermionic emission currents across an interface characterized by a distribution of barrier heights. Additionally, it is possible that the distribution itself is voltage dependent. The current equation can be rewritten to include this distribution such that:

$$I(V_A) = A^* T^2 \left[ \exp\left(\frac{q(V_A - I R_s)}{k_B T}\right) - 1 \right] \int_{-\infty}^{\infty} P(\phi_b^V) \exp\left(\frac{-q\phi_b^V}{k_B T}\right) d\phi_b^V$$

(2)

Where $P(\phi_b^V)$ represents the probability distribution of barrier heights apparent at the M-S interface under an applied voltage and must satisfy,
A consequence of a laterally varying barrier height is both an additional temperature and voltage dependence of the I-V characteristics. Werner and Güttler show that if thermionic emission over these regions is dominating, the M-S interface can be modeled as a single effective barrier height which is both temperature and voltage dependent according to:

\[
I(V_A) = A A^* T^2 \exp \left( \frac{-q \phi_{b}^{\text{eff}}(V,T)}{k_B T} \right) \left[ \exp \left( \frac{q(V_A - I R_S)}{k_B T} \right) - 1 \right]
\]  

(4)

Here, \( \phi_{b}^{\text{eff}}(V,T) \) is the effective barrier height. For SBD’s suffering from lateral inhomogeneity, values of zero-bias barrier height extracted from I-V measurements are considered equivalent to \( \phi_{b}^{\text{eff}}(0,T) \). An expression of the effective barrier height dependence on the lateral barrier distribution can be found by setting Equation (2) equal to (4).

\[
\phi_{b}^{\text{eff}}(V,T) = -\frac{k_B T}{q} \ln \left( \int_{-\infty}^{\infty} P(\phi_b^V) \exp \left( \frac{-q \phi_b^V}{k_B T} \right) d\phi_b^V \right)
\]  

(5)

Typically, the ideality factor is used to indicate that the observed I-V characteristics deviate from pure thermionic emission. However, in the context of an M-S interface with an inhomogeneous barrier, the ideality factor quantifies the voltage dependence of the distribution. Again, assuming thermionic emission is the dominant current conduction mechanism and that the ideality factor itself is not voltage dependent, Werner and Güttler showed that the effective barrier height voltage dependence at a fixed temperature can be found by setting Equation (1) equal to (4). This results in the following,

\[
\phi_{b}^{\text{eff}}(V,T) = \left(1 - \frac{1}{\eta(T)}\right) \cdot V + \phi_{b0}(T)
\]  

(6)

Here \( \phi_{b0}(T) \) and \( \eta(T) \) are the values of zero-bias effective barrier height and ideality factor at the measurement temperature, \( T \), from experimental I-V measurements, respectively. We can see that for SBD’s with an ideality factor of 1 the effective barrier is voltage independent, otherwise it will increase linearly with the quantity \( 1 - 1/\eta(T) \). From Equations (5) and (6), work can be done to relate a proposed probability distribution and its voltage dependence to experimentally extracted values of effective barrier height and ideality factor, respectively.

By assuming the interface can be described by a single Gaussian distribution, Werner and Güttler show that the experimentally extracted values of effective barrier height and ideality factor from a range of temperatures can be plotted according to Equations (14) and (17) in [7], respectively. This results in linear trends which can be fit to determine the Gaussian mean and standard deviation along with the voltage dependence of these parameters. Using the same process, Chand and Kumar [8, 9] showed that in cases where the effective barrier height and ideality factor plots yielded multiple regions of linearity, the lateral inhomogeneity can be described by multiple Gaussian distributions. However, for this to be true only one
distribution should be active at each temperature range (non-overlapping distributions) and that data analysis will yield increasingly larger Gaussian means at higher temperatures. If experimental results do not follow this, Jiang et al. [10] showed that the integral in Equation (5) could be re-evaluated with a summation of Gaussian distributions and experimental data could be fit using sets of Gaussian mean, standard deviation and weighting factors as input parameters in an iterative solver.

It was found that application of the above methods either resulted in poor fitting or violations of the underlying assumptions. Instead, good agreement with experimentally extracted zero-bias effective barrier heights across a wide temperature range could be made by modeling the interface with a modified log-normal distribution. Additionally, the ideality factor data was used according to Equation (6) to evaluate the effective barrier height at increasingly larger voltages and graphically show the evolution of the probability distribution. The results suggest that a value for the flat band barrier height can be determined, showing good agreement with that extracted from capacitance vs. voltage (C-V) measurements. Additionally, values of effective barrier height and ideality factor extracted from the additional linear region apparent at temperature <256 K are evaluated with the same process showing that this portion of the I-V characteristics can be considered to come from a portion of the M-S interface with differing Schottky characteristics.

5 Experimental Procedure
The sample used in this work is an n-type GaN film grown on a sapphire substrate by MOCVD. Film thickness is 1 um with an n-type doping of $3 \times 10^{16} \text{cm}^{-3}$ extracted from C-V measurements. The sample was first sonicated in acetone then isopropyl alcohol for 10 minutes and rinsed in deionized water. Then a bath of aqua regia was used to remove metal ions from the surface of the sample followed by a 49% HF bath to remove any surface oxide layer, each sitting at room temperature for 10 minutes. Again the sample was rinsed in deionized water followed by a nitrogen drying step. Next, an optical lithography process and 1 min oxide removal BOE dip followed by a Ti/Al/Ni/Ag (30/100/50/150 nm) metallization stack deposited by E-beam was used to define the top-surface ohmic contacts. The ohmic contacts were annealed at 700 °C under a continuous flow of dry $N_2$ for 5 minutes. Schottky contacts were formed with circular Ni/Ag (50/150 nm) E-beam deposited films with no subsequent heat treatment. After fabrication, the sample was mounted to a temperature controlled stage in an MMR microprobe station with a CTI Model 22 cryostat where measurements were performed between 50 and 400K in steps of 4 K on a 190 μm diameter sample. After temperature stabilized to within ±0.1 K of the target temperature for >30 s, the I-V characteristics of the reported device was measured by a Keithley 2400. C-V characteristics were recorded over the same temperature range using a DC sweep from 0 to -5 V and a 1MHz probing signal from a SULA fast capacitance meter.

6 Results and Discussion
The results of the I-V measurements taken at temperatures between 50 and 400 K are shown below in Figure 1. As Equation (1) predicts, when displayed on a semi-log plot each I-V measurement has a region of linearity characteristic of thermonic emission over a barrier followed by a roll-over at higher currents (>10 μA) due to series resistance. Additionally, measurements made at low temperatures (<256 K) exhibit two regions of linearity and roll-over indicative of a parallel conduction path. It is assumed this additional region stems from a Schottky interface with characteristics that don’t allow it to dominate across the full temperature and voltage range, thus it is labeled the parallel Schottky (PS) region. One possible source of this phenomenon is a region with a voltage dependent barrier height which causes pinch off resulting
in higher barrier regions to dominate as bias is increased. Later analysis will show that extracted values of ideality factor support this argument. In light of this additional region, Equation (1) is modified to include the current contribution from parallel SBD’s at the same M-S interface.

$$I(V_A) = A A^* T^2 \sum_{i=1}^{n} \exp \left( -\frac{q \phi_{b_i}^{eff}(0, T)}{kT} \right) \left[ \exp \left( \frac{q(V_A - I R_{s_i})}{\eta_i k_B T} \right) - 1 \right]$$  \hspace{1cm} (7)

Here, the variables $\phi_{b_i}^{eff}(0, T)$, $\eta_i$, and $R_{s_i}$ are the zero-bias effective barrier height, ideality factor and series resistance of the $i$-th SBD respectively and in the case of the reported sample, $n$ is 2 for I-V measurements from 50 to 256 K, otherwise only one set of parameters was required and $n$ is 1. Determination of these values was accomplished by using them as the input parameters to a damped least-square fitting procedure utilizing Equation (7). Fitting the full current and voltage range produced values of $R^2 > 0.999$ for I-V measurements at each temperature. The zero-bias effective barrier height and ideality factor values which provide the best fit are plotted versus temperature in Figure 2(A) and (B), respectively.
In both Figure 2 (A) and (B), parameters extracted from the PS region of the I-V curve are denoted by a downward triangle (▽) while all others are represented by an upward triangle (△). Extracted values of the effective barrier height were also plotted according to Werner and Güttler’s single Gaussian distribution model, Equation (14) in [7], shown as the red data points in Figure 2(A). Reviewing the I-V curves, it is likely that at temperatures >350 K, extracted values of effective barrier height and ideality factor deviate from the actual value due to the dominance of series resistance. For this reason, values of effective barrier height and ideality factor extracted from I-V characteristics measure above 350 K were not used in subsequent fitting.

As discussed previously, if the interface is dominated by a single Gaussian distribution, plotting the effective barrier height vs. \((2k_B T)^{-1}\) would linearize the data across the full temperature range however, this is clearly not the case. Because this deviation implies the interface cannot be represented by a single Gaussian distribution, the effective barrier height vs. \((2k_B T)^{-1}\) data was fit with multiple lines. Fitting the barriers extracted from all but the PS region indicated the existence of three Gaussian distributions according to Chand and Kumar’s method [8, 9]. However, calculated values of each distribution’s mean did not increase monotonically with temperature and each of the distributions implied significant overlap thus violating the underlying assumptions. Finally, an attempt was made to fit the extracted barrier temperature dependence by iteratively varying the mean, standard deviation and weight of two Gaussian distributions following work done by Jiang et al. [10]. Good agreement was found however, the results indicated that one of the distributions was characterized by a mean of 1.4 eV, a value larger than the theoretically predicted barrier height at a Ni/GaN interface (~1.2 eV).

Broadly speaking, an arbitrary distribution of barrier heights could be used to fit the effective barrier height data according to Equation (5) however, the dominance of lower barrier regions in the I-V relationship effectively hides contributions from higher barrier regions at the M-S interface. Unless inhomogeneity is minimal or measurements are taken at high enough temperature, values of effective barrier height indicative of the higher barrier regions will not be observed. Thus, the density of the unobserved barrier heights become imperceptible and a single optimal form of the distribution cannot be
found. By constraining \( P(\phi_b^V) \) with a defined probability density function, the form of the distribution outside of the observed range will be defined by the observed data and an optimal solution can be reached. In this work it was found that the range of effective barrier heights could be appropriately fit with a single modified log-normal distribution defined by Equation (8) below.

\[
P(\phi_b^V) = \frac{1}{C(-\phi_b^V + A)\sqrt{2\pi}} \exp\left(\frac{-\left[\ln(-\phi_b^V + A) - B\right]^2}{2C^2}\right)
\]

Here \( A, B, \) and \( C \) are used as input parameters to an iterative fitting routine that minimizes the error between generated effective barrier heights according to Equation (5) and the experimentally determined values. In addition to these parameters, the lower limit of integration (\( \phi_{LL} \)) was used as an input to the fitting procedure while ensuring that Equation (3) was met by scaling the resulting distribution on each iteration. This effectively estimates the form of the distribution at temperatures below what was measured but instead of requiring the distribution to continue infinitely to negative values of effective barrier height, it is weighted to zero below \( \phi_{LL} \).

The fitting was first applied to effective barrier heights extracted from all but the PS region, represented with \( \Delta \) in Figure 2(A), and the result is overlaid, shown as dashed lines. The good agreement with the experimental data indicates that a single modified log-normal distribution can be used to describe the inhomogeneous nature of the Ni/GaN SBD. The resultant fitting parameters \( \phi_{LL}, A, B, \) and \( C \) used to fit the effective barrier heights extracted from all but the PS region are 11.5 meV, 0.94, -1.76 and 0.20 respectively.

With an appropriate probability density function established, the voltage dependence of the distribution can be examined. Continuing with the parameters extracted from all but the PS region, effective barrier height vs. temperature plots are generated at incremental steps in voltage using Equation (6) and extracted values of ideality factor. In Figure 3(A), values of effective barrier height are evaluated in steps of 100 mV from 0-600 mV, shown as scatter plots, while the best fit effective barrier height curves from are shown as solid lines. The modified log-normal fitting procedure was repeated for each voltage step and the resulting probability distribution set is shown in Figure 3(B).

![Figure 3. (A) The effective barrier height temperature dependence generated from extracted values of zero-bias effective barrier height and ideality factor according to Equation (6) in steps of 100 mV from 0 to 600 mV (scatter). Fitting each set of](image)
data with the modified log-normal distribution resulted in the solid lines of best fit. (B) Normalized best fit probability function curves from the same voltage range. [(A) and (B) Single Column Fitting Images]

Referring to the calculated set of effective barrier heights in Figure 3(A), the data suggests that as the forward voltage is increased, regions at the M-S interface characteristic of lower effective barrier height (<0.65 eV) are strongly perturbed upward to higher values while those indicative of a higher effective barrier height are only slight perturbed as voltage is increased. Physically, this effect is consistent with the model proposed by Tung [4] where pinning at the M-S interface can induce a voltage-dependent conduction band saddle-point within the semiconductor. This saddle-point can become more strongly affected by voltage when the associated ‘patch’ is small and/or when strong pinning is present.

The resulting normalized best fit barrier distribution at each voltage step is shown in Figure 3(B). In the plot we can see that as the voltage is increased, the distribution tails on both sides of the peak move toward each other and the form begins to converge to a prominent barrier value. On the low side of the distribution this is expected, assuming barrier ‘pinch-off’ is occurring however, this cannot explain the behavior of the distribution tail on the high side. As mentioned earlier, the temperature dependence of the effective barrier height is influenced more heavily by lower regions of barrier height according to Equation (5). As the effective barrier height is generated at higher voltages, the trend begins to flatten out and the effect that lower barrier regions typically have is minimized. Thus, as the voltage is increased and the range of effective barrier heights begins to converge, the fitting procedure can more accurately represent the high side of the distribution.

Comparing the barrier distribution at 600 mV with flat-band barrier heights extracted from C-V measurements, it becomes apparent that the value at which the probability distribution converges is the flat-band barrier height.

Capacitance vs. voltage measurements were taken from 50-400 K in steps of 4 K from zero bias to -5 V. Below in Figure 4(A), the measured capacitance versus voltage characteristics have been replotted to show the linear $A^2/C^2$ trends which are used to extract flat-band barrier height from the extrapolated value of the x-intercept according to Equation (9).

$$\phi_B^{CV} = V_{FB} + \frac{k_B T}{q} \ln(N_C/N_D) + k_B T/q$$

Figure 4. The (A) $A^2/C^2$ data calculated from C-V measurements and (B) the values of flat-band barrier height calculated at each temperature. The previously calculated barrier distribution at 0.6 V from I-V measurements is compared. [(A) and (B) Single Column Fitting Images]
Here, \( V_{FB} \) is the voltage required to induce flatband conditions and is equal to the extrapolated value of the x-intercept on the \( A^2/C^2 \) plot. \( N_C \) is the temperature dependent conduction band density of states calculated from \( 4.3E14 \cdot T^{3/2} \), and the effective free carrier concentration, \( N_D \), is calculated from the slope of the \( A^2/C^2 \) plot according to Equation (10). The value \( \varepsilon_r \) is the dielectric constant of GaN (8.9) and \( \varepsilon_0 \) is the permittivity in vacuum. Flat-band barrier heights calculated from the extrapolated values of \( V_{FB} \) are shown in Figure 4(B) versus temperature. On the right side of the graph, the barrier distribution calculated for effective barrier heights at 0.6 V is plotted for comparison. The effective barrier distribution peak occurs at 0.77 eV and the extracted values of flat-band barrier height are 0.77±0.02 eV across the full temperature range. Good agreement between these two plots shows that the value at which the barrier distribution begins to converge is in fact the flat-band barrier height.

To understand the behavior of the PS region, the effective barrier heights were analyzed using the process outlined above. However, subsequent calculations of the effective barriers at increased voltages according to Equation (6) had interesting effects. Figure 5 shows the evolution of the effective barriers extracted from the PS region (▼) as compared to those extracted from I-V characteristics outside of this region (▲).

The zero-bias barriers extracted from the PS region (▼) increase with temperature until \( \sim250 \) K at which point the parallel conduction is no longer detectable in the I-V characteristics. Because the lower barrier region will dominate the I-V characteristics, it's theorized that the PS region disappears because the associated barrier height is the same as or larger than other areas at the M-S interface. When voltage is increased, as shown in the figure above, the effective barriers extracted from the PS region (▼) increases and as the trend moves upward, the point at which it crosses those extracted from outside the PS region (▲) occurs at increasingly lower temperatures. Accordingly, this implies that the PS region within each I-
V measurement should transition at lower voltages as the temperature is increased. Reviewing the I-V characteristics in Figure 1, it can be seen that this is indeed the case. Similar to Tung’s model [4], physically this effect could be caused by multiple patches at the M-S interface, each with characteristics that induce different voltage and temperature dependencies including size, pinning level and neighboring barrier properties.

7 Conclusion
In this work, we presented Ni/GaN Schottky diode I-V characteristics which could not be explained by the single Gaussian model proposed by Werner and Güttler [7] or multi-Gaussian models proposed by Chand and Kumar [8, 9] or Jiang [10]. To explain the temperature and voltage dependent effective barrier height behavior, a modified log-normal distribution is utilized and shows good agreement with experimental data. Next, it was found that subsequent calculations of the effective barrier height at increased voltages could be well explained using this distribution. Analysis of the probability distribution at these voltages revealed that the trend begins to converge on a prominent barrier height (0.77 eV) which agrees well with that extrapolated from C-V measurements under flat-band conditions (0.77±.02 eV). Finally, examination of the barriers extracted from the PS region of the I-V measurements reveal its behavior is indicative of an additional Schottky region characterize by a lower zero-bias barrier and stronger voltage dependence compared to those extracted outside of this region.
